ABSTRACT

Software companies or open source organizations often release their applications in different languages to address business requirements such as platform independence. To produce the same applications in different languages, existing applications already in one language such as Java are translated to applications in a different language such as C#. To translate applications from one language (L_1) to another language (L_2), programmers often use automatic translation tools. These translation tools use Application Programming Interface (API) mapping relations from L_1 to L_2 as a basis for translation. It is essential that the API methods of L_1 and their mapped API methods of L_2 (as described by API mapping relations) exhibit the same behavior, since any inconsistencies among these mapping relations could result in behavior differences and accumulate to defects in translated appliations. Therefore, to detect behavioral differences between API methods described in mapping relations, and thereby to effectively translate applications, we propose the first novel approach, called *TeMAPI* (**Te**sting **M**apping relations of **API**s). In particular, given a translation tool, TeMAPI automatically generates test cases that expose differences among mapping relations described in the tool. To show the effectiveness of our approach, we applied our approach on five popular translation tools. The results show that TeMAPI effectively detects various behavioral differences among mapping relations. We summarize detected differences as eight findings and their implications. Our approach enables these findings that can improve effectiveness of translation tools, and also assist programmers in understanding the differences among API methods between Java and C#.

1. INTRODUCTION

Since the inception of computer science, many programming languages (*e.g.*, Cobol, Fortran, or Java) have been introduced to serve specific requirements[1]. For example, Cobol is introduced specifically for developing business applications. In general, software companies or open source organizations often release their applications in different languages to survive in competing markets and to address various business requirements such as platform in-

dependence. A recent study [9] shows that nearly one third applications have multiple editions in different languages. A natural way to implement a application in a different language is to translate from existing applications. For example, Lucene.Net was translated from Java Lucene based on its website[2]. As another example, the NeoDatis object database as also translated form Java to C# based on its website[3]. The primary goal of such translation is to provide applications that both exhibit the same behavior.

As existing applications typically use API libraries, it is essential to understand API mapping relations of one programming language, referred to as L_1, to another language, referred to as L_2 when translating applications from L_1 to L_2. As pointed out by our previous work [25], API mapping relations can be complicated. In some cases, programmers may fail to find a existing class that has the same behavior in the other language. For example, Figures 1 and 2 show two methods implemented in db4o[4] of its Java version and its C# version, respectively. When translating the Java code shown in Figure 1 into C#, programmers of db4o may fail to find an existing C# class that have the same behaviors with the `ByteArrayInputStream` class in Java, so they implement a C# class with the same name to hide the behavior difference. Behavior differences of mapped API elements (*i.e.*, classes, methods, and fields) may occur in many places. To relief efforts, programmers of db4o developed their own translation tool, called sharpen[5], for translating db4o from java to C#. In particular, sharpen systematically replaces all API elements in Java with equivalent elements in C# to ensure that translated C# applications have the same behaviors with original ones.

In practice, programmers may fail to hide some behavior differences of mapped API elements. These behavior differences are harmful since they may accumulate and cause serious defects in translated applications silently. It is desirable to detect these behavior differences, but existing approaches [11, 13] cannot detect such differences effectively with four major reasons. (1) Existing approaches require both the versions under consideration belong to

Figure 4: Translated C# code by JLCA.

the same language, but in our context, both versions belong to different languages, making these existing approaches inapplicable. (2) The interfaces of two mapped API methods can be different, and one API methods can be mapped to multiple API methods. For example, as shown in Figure 3, JLCA[6] translates the `java.net.DatagramSocket.receive(DatagramPacket)` method in Java into multiple C# elements as shown in Figure 4. (3) Detecting behavior differences from existing applications address the problem partially since applications typically use only a small portion of API elements.

To address these preceding issues, we propose a novel approach, called TeMAPI (**Te**sting **Ma**pping relations of **API**s), that generates test cases to detect behavioral differences among API mapping relations automatically. In particular, TeMAPI generates test cases on one version App_1 of the application (in a language) and translates those test cases into the other language L_2. TeMAPI next applies translated test cases on the other version App_2 to detect behavioral differences. In this paper, we primarily focus on behavioral differences that can be observed via return values of API methods or exceptions thrown by API methods. TeMAPI addresses three major technical challenges in effectively detecting behavioral differences. (1) It is challenging to extract API mapping relations from translation tools for testing since they may follow different styles to describe such relations. For example, Java2CSharp[7] uses mapping files; sharpen hard codes in source code; and commercial tools such as JLCA typically hide mapping relations in binary files. (2) Using a naive technique such as generating test cases with `null` values may not be significant in detecting behavioral differences among API mapping relations. Since we focus on object-oriented languages such as Java or C#, to detect behavioral differences, generated test cases need to exercise various object states, which can be achieved using method-call sequences. To address this issue, TeMAPI leverages two existing state-of-the-art test generation techniques: random [16] and dynamic-symbolic-execution-based [6, 10, 19]. (3) Generating test cases on App_1 and applying those test cases on App_2 may not exercise many behaviors of API methods in App_2, thereby related defects cannot be detected. To address this issue, TeMAPI uses a round-trip technique that also generates test cases on App_2 and applies them on App_1. We describe more details of our approach and how we address these challenges in subsequent sections.

This paper makes the following major contributions:

- A novel approach, called TeMAPI, that automatically generates test cases that detect behavioral differences among API mapping relations. Given a translation tool, TeMAPI detects behavior differences of its all API mapping relations automatically. It is important to detect these behavior differences, since they can introduce defects in translated code silently.
- Test adequacy criteria proposed for generating sufficient test

cases to test API mapping. TeMAPI targets at generating adequate test cases that can reveal all behaviors of API methods to test their mapping relations.
- A tool implemented for TeMAPI and three evaluations on 5 translation tools that include 3 Java-to-C# tools and 2 C#-to-Java tools. The results show that various factors such as null values, string values, input ranges, different understanding, exception handling, static values, cast statements, and method sequences can lead to behavior differences of mapped API methods. Based on the results, we further analyze the implications of these factors for programmers and for translation tool developers.

The rest of this paper is organized as follows. Section 2 presents an illustrative example. Section 3 presents our approach. Section 4 presents our evaluation results. Section 5 discusses issues of our approach. Section 6 presents related work. Section 7 concludes.

2. EXAMPLE

We next present major steps in our approach for detecting the behavioral differences of mapped API elements. In particular, we use the `java.io.BufferedInputStream` class and the JLCA translation tool as illustrative examples.

Translating synthesized wrapper methods. As described by its documentation[8], the `BufferedInputStream` class in Java has 5 fields, 2 constructors, and 8 methods. To fully explore the behaviors of the class, TeMAPI synthesizes a wrapper method for each field and each method given each constructor. For example, given the `BufferedInputStream(InputStream)` constructor, TeMAPI synthesizes the wrapper method as follows for the `skip(long)` method:

```
public long testskip24nm(long m0,InputStream c0){
  BufferedInputStream obj = new BufferedInputStream(c0);
  return obj.skip(m0);
}
```

Each wrapper method check the return value of only one API method or field. If outputs are different given the same inputs, it is easy to locate the method or field with behavior differences and to find the inputs that cause behavior differences. TeMAPI next uses JLCA and translates synthesized wrapper from Java to C#.

Handling compilation errors. In general, a translation tool may not include mapping relations for all API methods of a language. Therefore, translated wrapper methods can have compilation errors. TeMAPI parses translated wrapper methods and removes all wrapper methods with compilation errors. For example, following is the translated C# `testskip24nm` method:

```
public virtual long testskip24nm(long m0, Stream c0){
  BufferedStream obj = new BufferedStream(c0);
  BufferedStream temp_BufferedStream = obj;;
  Int64 temp_Int64 = temp_BufferedStream.Position;
  temp_Int64 = temp_BufferedStream.Seek(m0,
      System.IO.SeekOrigin.Current) - temp_Int64;
  return temp_Int64;
}
```

TeMAPI does not removes this method since it has no compilation errors. Although JLCA translates the `skip(long)` method into multiple methods, we can still test the mapping relation since all translated code is within the wrapper method and a translation tool does not change the signatures of a wrapper method.

Generating test cases. TeMAPI leverages various techniques to generate test cases for the remaining wrapper methods. For example, TeMAPI extends Pex [19], a state-of-the-art test generation technique, to record all inputs and their corresponding outputs generated for each translated wrapper method. Each input generated

[6]http://tinyurl.com/35o5mo7
[7]http://j2cstranslator.sourceforge.net/
[8]http://tinyurl.com/2bca7vh

by Pex exercises a unique feasible path in the wrapper method. For example, TeMAPI generates the following Java test case based on inputs generated by Pex.

```java
public void testskip24nm36(){
  try{
      sketch.Test_java_io_BufferedInputStream obj =
          new sketch.Test_java_io_BufferedInputStream();
      long m0 = java.lang.Long.valueOf(
                   "-9223372036582079488").longValue();
      InputStream c0 = new InputStream(null);
      obj.testskip24nm(m0,c0);
  }catch(java.io.IOException e){
      Assert.assertTrue(true);return;
  }
  Assert.assertTrue(false);
}
```

This test case fails, since given the preceding inputs, the `skip(long)` method does not throw any exceptions as the translated C# code does. Thus TeMAPI detects a behavioral difference between the `skip(long)` method in Java and its mapped C# API methods defined by JLCA.

Besides Pex, TeMAPI also extends Randoop [16] to generate invocation sequences. TeMAPI extracts the list of translated wrapper methods without compilation errors, and analyzes synthesized wrappers for a list of translatable API methods and fields. When generating test cases, TeMAPI limits the search scope of Randoop, so that each generate test case invoke only translatable API methods and fields. For example, a generated Java test case is as follows:

```java
public void test413() throws Throwable{
  ...
  ByteArrayInputStream var2=new ByteArrayInputStream(...);
  var2.close();
  int var5=var2.available();
  assertTrue(var5 == 1);
}
```

TeMAPI next uses JLCA and translates the generated Java test case from Java to C#. As each wrapper method invokes only translatable API elements, we increase the chance of translating successfully. The translated C# test case is as follows:

```java
public void test413() throws Throwable{
  ...
  MemoryStream var2 = new MemoryStream(...);
  var2.close();
  long available = var2.Length - var2.Position;
  int var5 = (int) available;
  UnitTool.assertTrue(var5 == 1);
}
```

The preceding Java test case gets passed, but the C# test case get failed. We find that Java allows programmers to access a stream even if the stream is closed, so the preceding Java test case run successfully. C# does not allow such accesses, so the preceding C# test case fails with `ObjectDisposedException`. This example motivates our basic idea of generating test cases in one language and translating those test cases into another language for detecting differences among API mapping relations. We next present details of our approach.

3. APPROACH

Given a translation tool between Java and C#, TeMAPI generates various test cases to reveal behavior differences of the tool's API mapping relations. Figure 5 shows the overview of TeMAPI. It is able to test not only mapping relations of a single API class but also mapping relations of multiple API classes.

3.1 Synthesizing Wrappers for Translation

Given a translation tool, TeMAPI first extracts its API mapping relations. To deal with the different style problem described in Section 1, TeMAPI does not extract API mapping relations directly from translation tools, but chooses to analyze translated code

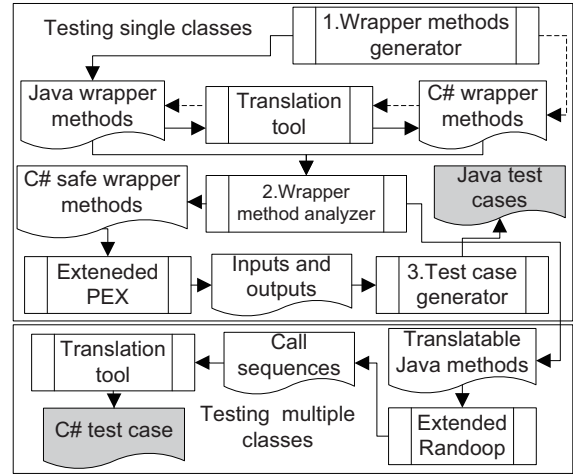

Figure 5: Overview of TeMAPI

of translation tools. Translating existing applications address the problem partially for two major reasons. (1) Many API mapping relations cannot be covered, since applications typically use a small portion of API classes. (2) In existing applications, a single method often invokes multiple API methods. When an API method is translated into multiple methods, it is difficult to extract mapping relations. For the preceding reasons, TeMAPI relies on the reflection technique [12] provided by both Java and C# to synthesize wrapper methods for translation. Each wrapper method uses only one field or method, so TeMAPI can extract translatable API elements in the finest level. In particular, TeMAPI synthesizes wrapper methods for static fields and methods as follows:

Static fields. Given a public static field `f` of a class `C` whose type is `T`, TeMAPI synthesizes a getter as follows:

```
public T TestGet|f.name||no|(){ return C.f; }
```

If `f` is not a constant, TeMAPI synthesizes a setter as follows:

```
public void TestSet|f.name||no|(T v){ C.f = v; }
```

Static methods. Given a public static method `m(T1 p1,...,Tn pn)` of a class `C` whose return type is `Tm`, TeMAPI synthesizes a wrapper method as follows:

```
public Tm Test|m.name||no|(T1 m1,..., Tn mn){
  return C.m(m1,..., mn); }
```

When TeMAPI synthesizes wrapper methods for non-static fields or methods, it takes constructor into considerations:

Non-static fields. Given a public non-static field `f` of a class `C` whose type is `T`, TeMAPI synthesizes a getter for each constructor `C(T1 p1,..., Tn pn)` of `C` as follows:

```
public T TestGet|f.name||no|(T1 c1,..., Tn cn){
  C obj = new C(c1,..., cn);
  return obj.f; }
```

If `f` is not a constant, TeMAPI synthesizes a setter as follows:

```
public void TestSet|f.name||no|(T1 c1,..., Tn cn){
  C obj = new C(c1,..., cn);
  obj.f = v; }
```

Here, "`|f.name|`" denotes the name of `f`, and "`|no|`" denotes the corresponding number of synthesized wrapper method.

Non-static methods. Given a public non-static method `m(T1 p1,...,Tn pn)` of a class `C` whose return type is `Tm`, TeMAPI synthesizes a wrapper method for each constructor `C(Tv pv,..., Tt pt)` of `C` as follows:

```
public Tm Test|m.name||no|(T1 m1,..., Tn mn,
                           Tv cv, ..., Tt ct){
  C obj = new C(cv,..., ct);
  return obj.m(m1,..., mn); }
```

Here, "|m.name|" denotes the name of m(T1 p1,...,Tn pn).

TeMAPI put all synthesized wrapper methods for one API class C into one synthesized class. For a Java-to-C# tools, TeMAPI synthesizes wrapper methods in Java as shown by the solid line in Figure 5, and for a C#-to-Java tools, TeMAPI synthesizes wrapper methods in C# as shown by the dotted line in Figure 5. When synthesizing, TeMAPI ignores generic methods for simplicity. Besides, for C#, it ignores unsafe and delegate methods and methods whose parameters are marked as out or ref. Java does not have corresponding keywords, so existing tools typically do not translate them. After wrappers are synthesized, we translate them using a translation tool under analysis.

After synthesized code is translated, TeMAPI parses translated code and removes translated wrappers with compilation errors. For Java code, TeMAPI extends Eclipse's Java compiler for the list of compilation errors. For C# code, TeMAPI extracts the list of compilation errors through the automation and extensibility interfaces of Visual Studio. For Java-to-C# tools, we refer to the remaining C# wrappers as C# safe wrappers (safe wrappers for short). For C#-to-Java tools, we refer to the synthesized C# wrappers that can be translated without compilation errors as safe wrappers. As wrappers reveal behaviors of a given class at the finest level and expose interfaces of inputs and outputs, TeMAPI further uses safe wrappers to test single API classes (Section 3.2). Comparing safe wrappers with synthesized wrappers, TeMAPI can extracts the list of translatable API elements for a given translation tool. Using the list, TeMAPI further tests API multiple API classes (Section 3.3).

3.2 Testing Single API Classes

Pex [19] is a white-box test generation tool for .Net based on dynamic symbolic execution. Basically, Pex repeatedly executes a method under test, so that it explores all feasible paths of the method. To reduce the efforts to explore paths, Pex leverage various search strategies. For example, Xie *et al.* [22] propose a search strategy called Fitnex that uses state-dependent fitness values to guide path exploration of Pex.

TeMAPI extends Pex, so that it generates test cases for detecting behavior differences of single classes. In particular, for each API class, TeMAPI leverages Pex to search paths of each its safe wrapper method, and records the inputs and the corresponding output when Pex searches each path. Based on recorded inputs and outputs, TeMAPI generates Java test cases to ensure each mapped API elements produce the same output give the same inputs. To check outputs, TeMAPI checks whether their values are equal for primitive types and arrays, and checks whether each mapped fields are equal for objects. For example, TeMAPI records that given an empty object, the testappend175nm wrapper method in C# return a StringBuilder value whose Capacity is 16 and Length is 13, so TeMAPI generates a test case for the corresponding Java wrapper method as follows:

```
public void testappend175nm122(){
  sketch.Test_java_lang_StringBuffer obj =
      new sketch.Test_java_lang_StringBuffer();
  Object m0 = new Object();
  StringBuffer out = obj.testappend175nm(m0);
  Assert.assertEquals(16, out.capacity());
  Assert.assertEquals(13, out.length());
}
```

This test case fails, since here the capacity() method returns 34 and the length() method returns 24. Thus, TeMAPI detects two behavior differences between the java.lang.StringBuffer class in Java and the System.Text.StringBuilder class in C#.

We find that when Pex searches a path with some specific inputs, the method under test throws exceptions. For example, TeMAPI

Name	Version	Provider	Description
Java2CSharp	1.3.4	IBM (ILOG)	Java to C#
JLCA	3.0	Microsoft	Java to C#
sharpen	1.4.6	db4o	Java to C#
Net2Java	1.0	NetBean	C# to Java
VB & C# to Java converter	1.6	Tangible	C# to Java

Table 1: Subject tools

records that if the input of the TestvalueOf61sm wrapper method in C# is null, the method throws NullReferenceException, so it generates a Java test case to ensure the corresponding Java wrapper method also throws a mapped exception. To generate the Java test case, TeMAPI first finds the corresponding exceptions in Java by analyzing translated wrapper methods with synthesized code. For example, TeMAPI finds that the NullReferenceException class in C# is mapped to the NullPointerException class in Java with respect to the API mapping relations of Java2CSharp, so it generates a Java test case as follows:

```
public void testvalueOf61sm3(){
  try{
    sketch.Test_java_lang_String obj =
        new sketch.Test_java_lang_String();
    java.lang.Object m0 = null;
    obj.testvalueOf61sm(m0);
  }catch(java.lang.NullPointerException e){
    Assert.assertTrue(true);
    return;
  }
  Assert.assertTrue(false); }
```

This Java test case fails since the testvalueOf61sm method does not throw any exceptions given a null input. From this failed Java test case, TeMAPI detects the behavior difference between the java.lang.String.valueOf(Object) method in Java and the System.Object.ToString() method in C#, since the preceding two wrapper methods are for the two API methods only.

3.3 Testing Multiple Classes

As each wrapper method use only one field or one method of a given API class, it may lose some behavior differences that involve multiple classes. To test multiple classes, TeMAPI first extract translatable API elements by comparing safe wrappers with synthesized wrappers. For example, as shown in Section 2, the C# testskip24nm method is a safe wrapper method. TeMAPI then parses the testskip24nm method in Java, and adds the Buffered-InputStream(InputStream) constructor and the BufferedInputStream.skip(long) method as translatable API elements.

Randoop [16] is a test generation tool for Java. It randomly generates test cases based on already generated test cases in a feedback-directed manner. TeMAPI extends Randoop to test behavior differences that involve multiple classes. In particular, TeMAPI restricts the search scope of Randoop, so that its generated test cases use translatable API elements only although a test case can use multiple classes. After that, TeMAPI runs generated test cases and removes those failed test cases. We translate the remaining test case into C# using the translation tool under analysis. If such translation does not change behaviors, translated C# test cases should also get passed. Thus, TeMAPI is able to detect behavior differences that involve multiple classes, and Section 2 shows a detected one.

4. EVALUATIONS

We implemented a tool for TeMAPI and conducted evaluations using our tool to address the following research questions:

1. How effectively can existing translation tool translate API elements (Section 4.1)?
2. How effectively can our approach detect behavior differences of single API classes (Section 4.2)?

Type	No	Java2CSharp		JLCA		sharpen	
		M	%	M	%	M	%
sfg	16962	237	1.4%	3744	22.1%	47	0.3%

nm	190376	4	0.0%	6	0.0%
Total	194835	27	0.0%	396	0.2%

Table 3: Translation results of C#-to-Java tools

3. How effectively can our approach detect behavior differences of multiple API classes (Section 4.3)?

4. Can the our combination strategy helps achieve better coverage (Section 4.4)?

Table 1 shows the subject tools used in our evaluation. Column "Name" lists names of subject tools. In the rest of the paper, we refer to "VB & C# to Java converter" as converter for short. Column "Version" lists versions of subject tools. Column "Provider" lists companies of subject tools. Although all these tools are from commercial companies, Java2CSharp, sharpen, and Net2Java are all open source. Column "Description" lists main functionalities of subject tools. We choose these tools as subjects since we find that many programmer recommend these tools in various forums.

All evaluations were conducted on a PC with Intel Qual CPU @ 2.83GHz and 1.98M memory running Windows XP.

4.1 Translating Synthesized Wrappers

For Java-to-C# tools, we used TeMAPI to synthesize wrapper methods for all classes of J2SE 6.0[9]. As described in Section 3.1, when synthesizing, TeMAPI ignored all generic API methods. Table 2 shows the translation results. Column "Type" lists types of synthesized methods. In particular, "sfg" denotes getters of static fields; "sfs" denotes setters of static fields; "nfg" denotes getters of non-static fields; "nfs" denotes setters of non-static fields; "sm" denotes static methods; "nm" denotes non-static methods; and "Total" denotes the sums of all methods. Column "No" lists numbers of corresponding types of methods. Columns "Java2CSharp", "JLCA", and "sharpen" list the translation results of corresponding translation tools. For these columns, sub-column "M" lists number of translated wrapper methods without compilation errors, and sub-column "%" lists percentages from translated wrapper methods without compilation errors to total synthesized ones.

From the results of Table 2, we find that it is quite challenging for a translation tool to cover all API elements, since API elements are quite large in size. Although JLCA can translate 43678 wrapper methods, it covers only 22.4% of total wrapper methods since it fails to translate other API elements in the rest of wrapper methods. Even if an API element is translated, it can be translated to an API element with behavior differences. We find that developers of translation tools may already notice the problem of differences. For example, after JLCA translated synthesized code, it generated a report with many warning messages for behavior differences of translated API elements. One warning message is "Method 'java.lang.String.indexOf' was converted to 'System.String.IndexOf' which may throw an exception", but the report does not tell programmers when such an exceptions is thrown or how to deal with such exceptions. JLCA leaves these behavior differences to programmers.

For C#-to-Java translation tools, we used TeMAPI to synthesize wrapper methods for all classes of the .Net framework client profile[10]. As described in Section 3.1, besides generic methods,

TeMAPI also ignored methods whose parameters are marked with `out` or `ref`. Table 3 shows the translation results. Columns of Table 3 are of the same meanings with the columns of Table 2, but generated wrapper methods are in C#. TeMAPI synthesized almost the same size of wrapper methods as it synthesized for J2SE 6.0. From the results of Table 2, we find that both the two tool translate only quite a small portion of API elements. As described in the wikipedia[11], C# provides many features that Java does not have (e.g., partial class, reference parameters, output parameters, and named arguments). We suspect that a C#-to-Java translation tool needs take more effects on these issues, so many mapping relations of API elements are not addressed yet.

Comparing the translation results between Java-to-C# tools and C#-to-Java tools, we find that Java-to-C# tools cover much more API elements. To fully explore the translation results of Java-to-C# tools, we present the results at the package level in Table 4. Column "Name" lists names of Java packages. To save space, we omit the prefixes such as "java.", "javax.", and "org." if it does not introduce ambiguity. We also use short names for some packages. In particular, we use "acc." to denote the `javax.accessibility` package, "man." to denote the `javax.management` package, "java. sec." to denote the `java.security` package, and "javax.sec." to denote the `javax.security` package. We also omit 12 packages that are not covered by all the three tools (e.g., the `javax.rmi` package). Other columns of Table 4 are of the same meanings with the columns of Table 2. From the results of Table 4, we find that all the three translation tools cover the `java.io` package, the `java.lang` package, the `java.util` package, and the `java.net` package. The four packages seem to be quite important for most Java programs. Almost for all the packages, JLCA covers more API elements than the other two tools. In particular, JLCA covers GUI-related packages such as the `java.awt` package and the `javax.swing` package. As a result, JLCA can translate some Java programs with GUI interfaces whereas the other two tools cannot.

4.2 Testing Single Classes

To test behavior differences of single classes, TeMAPI leverages Pex to search internal paths for safe wrapper methods. These methods include the translated C# wrapper methods without compilation errors as shown in Table 2, and the synthesized C# wrapper methods that can be translated into Java without compilation errors as shown in Table 3. When Pex searches each wapper method, TeMAPI records the inputs and output for each path. Based on those inputs and outputs, TeMAPI generates Java test cases to ensure that synthesized wrapper methods and translated wrapper methods produce the same outputs given the same inputs. As it requires human interactions to test GUI related API elements, we filter out GUI related API elements (i.e., the `awt` package and the `swing` package) although JLCA is able to translate some classes of the two packages. In addition, when Pex searches methods without return values, we ignore those paths that do not throw any exceptions since we cannot generate Java test cases for them. We discuss this

Table 5: Results of testing single classes

issue in Section 5.

We run generated Java test cases, and Table 5 shows the results. Column "Name" lists names of translation tools. Column "Java" lists numbers of generated Java test cases. Columns "Error" lists numbers of test cases that throw un-handled exceptions. Columns "Failure" lists numbers of test cases that fail in assertion. For the two columns, sub-column "M" lists numbers of corresponding test cases, and sub-column "%" lists percentages from numbers of corresponding test cases to numbers of total generated test cases. From the results of Table 5, we find that totally only about half the generated Java test cases get passed. Among the five tools, sharpen achieves the lowest error and failure percentage. It seems that developers of sharpen put great efforts to hide behavior differences. The percentage of JLCA is also relatively low. The results is commendable since it translates much more API elements than the other tools. Totaly, about 50% test cases does not get passed. The results show the effectiveness of TeMAPI since these test cases indicate behavior differences.

For Java2CSharp, JLCA, and sharpen, we further present their testing results at the package level in Table 6. Column "Name" lists names of J2SE packages. For columns "Java2CSharp", "JLCA", and "sharpen", sub-column "R" lists numbers of generated Java test cases, and sub-column "%" lists percentages from test cases end with errors or failures to total test cases. From the results of Table 6, we find that for the `java.sql` package and the `java.util` package, all the tools suffer relatively high error/failure percentages, and for the `java.lang` package and the `java.math` package, all the tools achieve relatively low error/failure percentages. The results may reflect that some packages between Java and C# are more similar than others, so they can more easily mapped. We also find that for package the `java.text` package, the `javax.xml` package, and the `org.xml` package, JLCA achieves the lowest error/failure percentages among the five tools. The results may indicate that a translation tool can achieve better translation results if they carefully prepare mapping relations of API elements.

From the results of Table 5 and Table 6, we find that many generated Java tests do not get passed. To better understand behavior differences of mapped API elements, we manually inspected 3759

Java test cases that do not get passed. For Java2CSharp, JLCA, and sharpen, we investigate their test cases for the `java.lang` package. For tools such as Net2Java and converter, we inspect all their test cases since TeMAPI does not generate too many test cases for them. Our findings are as follows:

Finding 1: 36.8% test cases show the behavior differences caused by null inputs.

We find that Java API methods and their translated C# API methods can have behavior differences when inputs are null values. In some cases, a Java API method can accept null values, but its translated C# API method throws exceptions given a null value. One such example is shown in Section 2 (*i.e*, the `skip(long)` method in Java and its mapped C# methods). In some other cases, a Java API method throws exceptions given a null value, but its translated C# API method can accept null values. For example, JLCA translates the `java.lang.Integer.parseInt(String,int)` method in Java to the `System.Convert.ToInt32(string,int)` in C#. When the inputs of the Java method are null and 10, it throws `NumberFormatException`, but given the same inputs, the output of the C# method is 0. We notice that some translation tools can hide some differences caused by null inputs. For example, to hide the behavior difference of null inputs for the `valueOf(Object)` method as shown in Section 3.2, sharpen translates the method to its self-developed C# method, and thus hide the difference.

Implication 1: Although implementers of API libraries in different languages can come to agreements on functionalities of many API methods, behaviors for null inputs are typically controversial. Some translation tools try to hide the difference, but many such differences are still left to programmers as shown in our results. Therefor, programmers should be careful when inputs are null.

Finding 2: 22.3% test cases show the behavior differences caused by stored string values.

We find that string values stored in fields of Java classes and C# classes are typically different. The difference ranks as the second because each Java class has a `toString()` method and each C# class also has a `ToString()` method. Many translation tools map the two API methods, but the return values of the two methods are quite different in many cases. As another example, many API classes declare methods like `getName` or `getMessage`. These methods also return string values that can be quite different. In particular, we find that the `Message` fields of exceptions in C# often return informative messages. One such message is "Index was outside the bounds of the array" provided by the `System.IndexOutOfRangeException.Message` field. On the other hand, exceptions in Java often provide only null messages. Overall, we find that all the five tools do not hide the difference.

Implication 2: String fields of mapped classes in different languages typically store different values, but existing translation tool do not hide difference. Programmers should not rely on these values since they are typically different across languages.

Finding 3: 11.5% test cases show the behavior differences caused by illegal inputs or inputs out of ranges.

We find that API methods in Java seldom check whether their inputs are legal or out of range, whereas API methods in C# often do.

Table 6: Testing results of package level

For example, the `java.lang.Boolean.parseBoolean(String)` method in Java does not check illegal inputs, so it returns false given an input whose value is "test". Java2CSharp translates the Java method to the `System.Boolean.Parse(String)` method in C#. The C# method throws `FormatException` given the same input since it checks illegal inputs. As another example, the `java.lang.Double.shortValue()` method in Java accepts values that are larger than `Short.MAX_VALUE` (32767). JLCA maps the Java method to the `Convert.ToInt16(double)` method in C#. The C# method throws `OverflowException` when values are larger than 32767 since it checks whether inputs are too large.

Implication 3: API methods across languages may follow different standard to check their inputs for different considerations. If a tool translates code from a loose standard to a strict standard (*e.g.*, Java to C#), it can add extra code to strengthen the standard. If a tool translates code from a strict standard to a loose standard (*e.g.*, C# to Java), it will be difficult to hide the difference. When programmers migrate from one language to another, they should check whether a new language follow a strict standard or not.

Finding 4: 10.7% test cases show the behavior differences caused by different understanding.

We find that Java developers and C# developers may have different understanding for mapped API methods. For example, the `java.lang.StringBuffer.capacity()` method in Java returns "the current capacity of the String buffer", and the `System.Text.StringBuilder.Capacity` field in C# returns "the maximum number of characters that can be contained in the memory allocated by the current instance". JLCA maps the method in Java to the field in C#, and we find that in many cases they are of different values. For sample, given a string whose value is "0", the `capacity()` in Java returns 0, but the `Capacity` field in C# is 16. We notice that some differences of this type may indicate defects in translation tools. For example, Java2CSharp maps the `java.lang.Integer.toHexString(int)` method in Java to the `ILOG.J2CsMapping.Util.IlNumber.ToString(int,16)` method in C#. Given a integer whose value is -2147483648, the Java method returns "80000-000", but the C# method returns "\080000000". As another example, Java2CSharp maps the `Character.isJavaIdentifierPart(char)` method in Java to the `ILOG.J2CsMapping.Util.Character.IsCSharpIdentifierPart(char)` method in C#. Given a

input whose value is '\0', the Java method returns true, but the C# method return false. The two behavior differences were confirmed as bugs by developers of Java2CSharp.

Implication 4: Although implementers can come to agreement on functionalities of many API methods, they may have different understanding on functionalities of specific methods. Some differences of this type are confirmed as defects in translation tools. Programmers should test their translated code carefully since this type of differences are difficult to figure out.

Finding 5: 7.9% test cases show the behavior differences caused by exception handling.

We find that two mapped API methods can throw exceptions that are not mapped. For example, when indexes are out of bounds, the `java.lang.StringBuffer.insert(int,char)` method in Java throws `ArrayIndexOutofBoundsException`. Java2CSharp maps the methods to the `StringBuilder.Insert(int,char)` method in C# that throws `ArgumentOutOfRangeException` when indexes are out of bounds. As Java2CSharp maps `ArrayIndexOutofBoundsException` in Java to `IndexOutOfRangeException` in C#, the mapped C# method may fail to catch exceptions when indexes are out of bounds.

Implication 5: Implementer of API libraries may design quite different exception handling mechanism. This type of differences are quite challenge to hide for translation tools. Even if two methods are of the same functionality, programmers should notice that they may produce exceptions that are not mapped.

Finding 6: 2.8% test cases show the behavior differences caused by static values.

We find that mapped static fields may have different values. For example, the `java.lang.reflect.Modifier` class has many static fields to represent modifiers (*e.g.*, FINAL, PRIVATE and PROTECTED). Java2CSharp translates these fields to the fields of the `ILOG.J2CsMapping.Reflect` class. Although most mapped fields of the two class are of the same values, we find that fields such as VOLATILE and TRANSIENT are of different values. In addition, we find that different values sometimes reveal different ranges of data types. For example, `java.lang.Double.MAX_VALUE` in Java is 1.7976931348623157E+308, and `System.Double.MaxValue` in C# is 1.79769313486232E+308. Although the difference is not quite large, it can cause serious defects if a program needs highly accurate calculation results.

Implication 6: Implementer of API libraries may store different values in static fields. Even if two static fields have the same names, programmers should be aware of that they can have different values. The results also reveal that data types between Java and C# can have different boundaries. Programmers should be aware of this if they need highly accurate results.

The rest 7.9% test cases do not get passed since API methods can return random values or values that depend on time. For example, the `java.util.Random.nextDouble()` method in Java returns random values, and the `java.util.Date.getTime()` method returns the number of milliseconds since Jan. 1st, 1970, 00:00:00 GMT. As another example, each Java class has a `hashCode()` method, and each C# class has also a `GetHashCode()` method. Both the two methods return a hash code for the current object, so translation tools such as JLCA map the two methods. As a hand code is randomly generated, the two methods typically return different values. For these methods, TeMAPI can detect their behavior differences of inputs. For example, converter translates the `System.Random.Next(int)` method in C# to the `java.util.Random.nextInt(int)` method in Java. Given a integer whose value is 0, the C# method return 0, but the Java method throws `IllegalArgumentException` with a message: "n must be posi-

Name	API	Java	C#	Failure	
				M	%

sharpen	586	13532	936	456	48.7%
Total	9642	45547	4504	2813	62.5%

Table 7: Results of testing multiple classes

tive". However, as these methods return values randomly, we cannot conclude they have behavior differences even if their outputs are different, and we discuss this issue in Section 5.

4.3 Testing Multiple Classes

To test behavior differences involving multiple classes, TeMAPI leverages Randoop to generate test cases given the list of translatable API methods. In this experiment, we focus on Java-to-C# tools only, since C#-to-Java tools translate few API elements as shown in Table 2. For each Java-to-C# tools, TeMAPI extracts the list using the technique as described in Section 3.3. When generating test cases, TeMAPI extends Randoop, so that each generated test case use only translatable API methods. Randomly generated invocation sequences may not reflect API usages in true practice, and we discuss this issue in Section 5. After test cases are generated, TeMAPI removes some test cases to ensure that remaining test cases all get passed. After that, we use the corresponding translation tool to translate the remaining test cases from Java to C#. As the remaining Java test cases all get passed, translated C# test cases should also get passed.

Table 7 shows the results. Column "API" lists sizes of translatable API elements. Column "Java" lists numbers of Java test cases that run successfully. Column "C#" lists numbers of C# test cases. We notice that many Java test cases are not successfully translated into C# test cases. We find that two factors that are not general or not related with API migration: (1) to prepare inputs of translatable API methods may introduce API methods that are not translatable; (2) some code structures are complicated to translate, and we further discuss this issue in Section 5. Besides the two factors, we find one general factors for API translation.

Finding 7: Many translated test cases have compilation errors since Java API classes and their mapped C# classes have different inheritance relations.

We find that Java API classes can have quite different inheritance relations with their mapped C# API classes, and thus introduce compilation errors. For example, many compilation errors are introduced by cast statements, and such an example is as follows:

```
public void test87() throws Throwable{
  ...
  StringBufferInputStream var4=...;
  InputStreamReader var10=
    new InputStreamReader((InputStream)var4, var8);
}
```

As the two Java API classes are subclass and parent class, the test case gets passed. JLCA translates the Java test case into a C# test case as follows:

```
public void test87() throws Throwable{
  ...
  StringReader var4=...;
  StreamReader var10=
    new StreamReader((Stream)var4, var8);
}
```

As the two translated C# class have no inheritance relations, the translated C# test case has compilation errors.

Implication 7: It seems to be too strict to require that implementers of API libraries in different languages follow the same inheritance hierarchy, and it is also quite difficult for translation tools to hide the behavior difference. Programmers should deal with the difference carefully.

Column "Failure" lists failed C# test cases. We do not list numbers of test cases end with errors since C# does not separate errors from failures as Java does. Sub-column "M" lists numbers of test cases, and sub-column "%" lists percentages from failed test cases to total test cases.

From the results of Table 7, we find that JLCA achieves the best results among the five tools. For each tool, we further investigate the first 100 failed test cases, and we find that 93.3% failed test cases are accumulated by the found factors as shown in Section 4.2: 45.0% for ranges of parameters, 34.0% for string values, 5.3% for different understanding, 4.0% for exception handling, 3.0% for null inputs, 2.0% for values of static fields, and 0.3% for random values. We find that random strategy of generating invocation sequences affects the distribution. For example, as invocation sequences are random, inputs of many methods are out of range or illegal. Java API methods typically do not check inputs, so these test cases get passed, but translated C# test cases fail with various exceptions since C# API methods typically check inputs. Besides the preceding found factors, we find an additional factor as follows:

Finding 8: 3.3% test cases fail because of invocation sequences.

We find that random invocation sequences can violate specifications of API libraries. One type of such specification is described in our previous work [26]: closed resources should not be manipulated. Java sometimes allow programmers to violate such specifications although the return values can be meaningless. One such example is shown in Section 2. Besides invocation sequences that are related to specifications, we find that field accessibility also leads to failures of test cases. For example, a generated Java test case is as follows:

```
public void test423() throws Throwable{
  ...
  DateFormatSymbols var0=new DateFormatSymbols();
  String[] var16=new String[]...;
  var0.setShortMonths(var16);
}
```

JLCA translates the Java test case into a C# test case as follows:

```
public void test423() throws Throwable{
  ...
  DateTimeFormatInfo var0 =
  System.Globalization.DateTimeFormatInfo.CurrentInfo;
  String[] var16=new String[]...;
  var0.AbbreviatedMonthNames = var16;
}
```

The `var0.AbbreviatedMonthNames = var16` statement fails with `InvalidOperationException` since a constant value is assigned to `var0`.

Implication 8: Legal invocation sequences may become illegal after translation. The target language may be more strict to check invocation sequences, and other factors such as field accessibility can also cause behavior differences. In most cases, programmers should deal with the difference themselves.

The rest 3.0% test cases fail since mapped methods are not implemented yet. In particular, Java2CSharp maps API elements in Java to C# API elements that are not implemented yet. For example, Java2CSharp maps the `java.io.ObjectOutputStream` class in Java to the `ILOG.J2CsMapping.IO.IlObjectOutput-Stream` class in C# that is not implemented, and such mapping relations lead to `NotImplementException`. The experiment in Section 4.2 does not detect the difference since the specific exception is not mapped.

4.4 Coverage

Test coverage is a common criterion to measure the adequacy of test cases [27]. To investigate whether our combination strategy helps achieve better coverage from Java to C#, we conduct an

Class	Pex	Randoop	TeMAPI
ManagerNotRecognizedException	100%	100%	100%
ManagerNotSupportedException	100%	100%	100%
SaxAttributesSupport	78%	74%	80%
XmlSaxDefaultHandler	100%	94%	100%
XmlSAXDocumentManager	29%	17%	29%
XmlSaxLocatorImpl	83%	100%	100%
XmlSaxParserAdapter	100%	100%	100%
XmlSourceSupport	100%	56 %	100%

Table 8: Results of testing coverage

experiment on JLCA, and Table 8 shows the results. Is trick to extract coverage of API methods, especially in our context where most mapping relations are between J2SE and .NetFramework. For example, we find that coverage tools such as PartCover[12] rely on the `JITCompilationStarted` method[13] for notifications of called methods, and thus fail to extract coverage for many methods in .NetFramework since usually no notifications are received when these method are called. As a result, we choose the `org.xml` package in Java as the subject. JLCA generates eight classes as shown in Table 8, and translates some classes of the `org.xml` package in Java to the eight C# classes. Column "Class" shows the names of the eight classes. Column "Pex" lists achieved coverage if leveraging only Pex. Column "Randoop" lists achieved coverage if leveraging only Randoop. We limit the search scope of Randoop to the `org.xml` package, and translate generated Java test cases into C# using JLCA As Pex searches feasible paths and Randoop relies on random strategy, Pex achieves better coverage than Randoop except the `XmlSaxLocatorImpl` class. We find that Pex can fail to generate non-null values for some interfaces. For example, the parameter of the `XmlSaxLocatorImpl(XmlSaxLocator)` constructor is an interface. Pex generates only null inputs for the constructor, but Randoop casts a value to the interface. As a result, Randoop achieves better coverage on this class than Pex. Still, both Pex and Randoop do not achieve high coverage for some classes such as the `XmlSAXDocumentManager` class. We find that some methods of the class cannot be covered unless it reads a file. As both Pex and Randoop generates filenames randomly, these methods are not covered by either tool. Column "TeMAPI" lists achieved coverage if combining Pex and Randoop. We find that the combination achieves the best results for all classes.

To investigate whether our combination strategy helps achieve better coverage from C# to Java, we conduct an experiment on converter, and Table 9 shows the results. For similar consideration, we select several classes (*i.e.*, the `System.Collections.Array-List` class, the `System.Collections.Hashtable` class, the `System.Collections.Queue` class, and the `System.Collections.Stack` class). Table 9 shows coverage of their translated classes in Java. The four Java classes are decompiled by JAD[14]. To compile the four Java classes, we fix defects introduced during decompiling, and change their package names. Column "Class" shows the names of the four Java classes. Column "Pex" lists achieved coverage if leveraging only Pex. We use TeMAPI to generates Java test cases when Pex searches feasible paths. Column "Randoop" lists achieved coverage if leveraging only Randoop. From the perspective of the four Java classes, Pex also generates test cases randomly since it does not search their feasible paths. As a result, the achieved coverage shown in Table 9 are also half to half. Column "TeMAPI" lists achieved coverage if combining Pex and Randoop. We also find that the combination achieves the best results.

In summary, by combing Pex and Randoop, TeMAPI achieve

Class	Pex	Randoop	TeMAPI
HashTable	23%	15%	26%
LinkedList	32%	26%	37%
ArrayList	18%	25%	31%
Stack	21%	55%	55%

Table 9: Results of testing coverage

higher coverage than with single tools.

4.5 Summary

In summary, we find that API elements are quite large in size, and translation tools typically cover only a small set of API elements. Although existing translation tools already notice behavior differences of mapped API elements, many differences are left unsolved. In particular, TeMAPI detects that various factors such as null values, string values, ranges of inputs, different understanding, exception handling, and static values can lead to behavior differences for single API elements. The preceding factors can accumulate to behavior differences of multiple API elements. Besides, TeMAPI detects that other factors such as cast statements and invocation sequences can also lead to behavior differences of multiple API elements.

4.6 Threats to Validity

The threats to external validity include the representativeness of the subject tools. Although we applied our approach on 5 widely used translation tools, our approach is evaluated only on these limited tools. This threat could be reduced by introducing more subject tools in future work. The threats to internal validity include human factors for inspecting behavior differences from failed test cases. To reduce these threats, we inspected those test cases carefully. The threat could be further reduced by introducing more researchers to inspect detected differences.

5. DISCUSSION AND FUTURE WORK

We next discuss issues in our approach and describe how we address these issues in our future work.

Detecting more behavior difference. As shown in our evaluations, TeMAPI does not cover all feasible paths, so it may fail to reveal some behaviors. To detect more behavior differences, some directions seem promising. (1) We can test side effects or mock objects to test methods without return values. (2) To test API methods that return random values, we can check the distribution of their returned values. (3) To test methods that need to read files, we can generate test cases based on Java provides the Compatibility Kit (JCK)[15] where standard call sequences and files are prepared. (4) Other tools such as Cute [10] and JPF [20] may help generate more test case. We plan to explore these directions in future work.

Testing translation of code structures. As shown in our evaluations, translation tools may fail to translate if code structures are complicated. We notice that other translation tools encounter with similar problems. For example, Daniel *et al.* [3] propose an approach that tests refactory engines by comparing their refactored results given the same generated abstract syntax trees. The idea inspires our future work to testing code structures for translation tools by comparing the translation results given the same code structures.

6. RELATED WORK

Our approach is related to previous work on areas as follows:

API translation. To reduce efforts of language translation, researchers proposed various approaches to automate the process (*e.g.*, JSP to ASP [7], Cobol to Hibol [21], Cobol to Java [14], Smalltalk

---

to C [24], and Java to C# [4]). El-Ramly *et al.* [4] point out that API translation is an important part of language translation, and our previous work [25] mines API mapping relations from existing applications to improve the process. Besides language migration, others processes also involve API translation. For example, programmers often need to update applications with the latest version of API libraries, and the new version may contain breaking changes. Henkel and Diwan [8] proposed an approach that captures and replays API refactoring actions to update the client code. Xing and Stroulia [23] proposed an approach that recognizes the changes of APIs by comparing the differences between two versions of libraries. Balaban *et al.* [1] proposed an approach to migrate client code when mapping relations of libraries are available. As another example, programmers may translate applications from using one API library to another. Nita and Notkin [15] propose twinning to automate the process given that API mapping is specified. Our approach detects behavior differences between mapped API elements, and the results help preceding approaches translate applications without introducing new defects.

Language comparison. To reveal differences across Languages, researchers conducted various empirical comparisons on different languages. Garcia *et al.* [5] present a comparison study on six languages to reveal their differences of supporting generic programming. Prechelt [17] compares runtime performances of seven languages. Many books [2, 18] also compare differences across languages. To the best of our knowledge, no previous work systematically compares behavior differences of mapped API elements since API libraries typically provide many classes and methods. Our approach enables us to present such a report, complementing the previous reports and books.

7. CONCLUSION

API Mapping relations serve as a basis for automatic translation tools to translate applications from one language to another. However, original and translated applications can exhibit behavior differences due to inconsistencies among mapping relations. In this paper, we proposed an approach, called TeMAPI, that detects behavior differences of mapped API methods via testing. TeMAPI targets at generating test cases that covers all feasible paths and sequences to reveal behavior differences of both single methods and method sequences. We implemented a tool and conducted three evaluations on five translation tools to show the effectiveness of our approach. The results show that our approach detects various differences between mapped API methods. We further analyze these differences and their implications. We expect that our results can help improve existing translation tools and help programmers better understand differences of Java and C#.
